Questions to be addressed:

Among adults and children with acute thermal burns, does the use of one cooling modality and duration, compared with another, cause a change in clinical outcomes including pain, depth or size of burn, need for hospitalization, duration of hospital stay, or other?

Introduction/Overview:

A SAC Answer on this topic in June 2019, identified a moderate amount of evidence regarding duration of cooling. An ILCOR (International Liaison Committee on Resuscitation) review on the same topic in 2015 concluded that studies evaluating direction of cooling were primarily animal (pig) studies, which were not included in GRADE analysis. They concluded that a burn treatment should be to “cool thermal burns with cool or cold potable water as soon as possible and for at least 10 minutes. If cool or cold water is not available, a clean cool or cold, but not freezing compress can be useful as a substitute for cooling thermal burns. Care should be taken to monitor for hypothermia when cooling large burns.” The SAC Answer from 6-15-19 identified 8 studies on this topic since the 2015 ILCOR publication and is now converted to a Scientific Review.

**Scientific Foundation:**

Until recently, the literature has been sparse regarding whether first aid burn cooling improves outcomes. An ILCOR (International Liaison Committee on Resuscitation) review on this same topic in 2015 noted that studies identified evaluating duration of cooling were primarily animal (pig) studies, which were not included in GRADE analysis. ILCOR’s review found no evidence that cooling improves pain, very-low-quality evidence it may decrease burn depth, very-low-quality evidence that it may decrease admission rates and hospital length of stay but did not affect need for advanced care. Their overall recommendation was: first aid providers should actively cool thermal burns. They noted that results from studies included suggested a minimum of 10 minutes of cooling, but they could not recommend a specific temperature or method of cooling. With the ILCOR summary from 2015 as the starting point, the last 5 years of literature was searched to determine outcomes regarding burn cooling.

This review identified 2 randomized control trials (RCT), 4 observational cohort (2 prospective, 2 retrospective), and 2 statistical modeling studies that have been published in the last 5 years relevant to this question. The first RCT was unblinded and looked at acute effects of local cold therapy on superficial burns. They found very transient improvements in microcirculation, edema formation, and histomorphology but cold therapy was ineffective across all measured outcomes after the 30-minute mark. The second RCT evaluated a comparison of three different cooling methods. They compared 20 minutes of cool tap water and two commercial burn dressing products that contain tea tree oil (Burnshield and Burn Cool Spray). All three methods were found to improve pain scores. The cool tap water was able to cool the skin significantly more than the burn dressings. They also found a correlation between temperature of tap water and pain scores.

There were two statistical model studies: one estimating the time and temperature relationship that would cause deep-partial thickness burns (second degree burns) and the other analyzing skin injury from hot spills onto various forms of clothing. The former study found that cooling with tap water increased exposure duration and temperature required to cause deeper burns. For example: if exposed to a 200-degree F scald, second degree burns would develop after 4.6 seconds exposure compared to 7.2 seconds exposure if scald was treated with cool running tap water. The latter study was able to highlight the importance of clothing removal as fast as possible, recommending within the first 2-3 seconds. The thickness of the clothing, skin thickness, and temperature of the water correlated with time to more severe injuries.

As for the observational studies, there were four studies found. The first evaluated 168 Lagos, Nigeria patients prospectively. This study supports cool running water: there were lower complications rates, decreased deep burn percentages, and less need for skin grafting. Surprisingly though, they did find a slightly higher mortality rate in the water lavage group. The second study retrospectively evaluated scald burns in 730 children younger than 14 that required hospitalization in an Australia and New Zealand burn registry. This study as well supports burn cooling. They found shorter hospital length of stay but no difference in need for surgery. The authors highlighted need for better first aid education as only 1/5 of patients received adequate burn cooling (20 minutes of cool running water) despite almost 90% receiving some form of prehospital cooling. The data from this study recommends targeting prevention programs aimed...
at children aged 0-2 years old (median age of cohort was 2 years old with 70% of total study population between 0-2 years). The third study analyzed 2320 patients retrospectively from that same Australia and New Zealand burn registry, this time for ages greater than 16. The study found 13% reduction in skin grafting, 48% reduction in ICU admission, and 18% reduction in hospital length of stay when adequate burn cooling (20 minutes of cool running water) was provided. It also showed a dose-response relationship with length of cooling, with benefit anywhere from 10 minutes to 40 minutes. Longer duration greater than 40 minutes may cause harm. The final study evaluated 4918 patients prospectively for clinical outcomes after burn first aid. They found a statistically significant reduction in burn depth but not reduction in total body surface area (TBSA) or need for grafting. Those that were grafted required 15% less area grafted if they received adequate first aid. Those receiving adequate first aid had 10% reduction in recovery time.

Overall these studies did show benefit from burn cooling. They all used the standard of 20 minutes cool running water within the first 3 hours of injury as their definition of “adequate first aid”. As discussed above, these studies are overall a low-certainty evidence with some mixed results. Nevertheless, the trend of these papers does show benefit to burn cooling. Despite lack of high certainty human studies, standard first aid treatment of thermal burns includes immediately removal of overlying clothing and jewelry and providing cool running water for a minimum of 20 minutes (within the first 3-hours post injury) to the burn.

In summary, evidence from this review supports recommendations that patients who sustain thermal burns should have overlying clothing and jewelry removed and cooling immediately by applying cool running water to the burn for a minimum of 10 minutes, ideally 20 minutes. If cool or cold water is not available, a clean cool or cold, but not freezing compress can be useful as a substitute for cooling thermal burns. There may be benefit in applying cool water up to 3 hours after the injury. Care should be taken to monitor for hypothermia when cooling large burns. There is also evidence of potential harm due to risk of hypothermia, especially in small children, from cooling beyond 40 minutes.
American Red Cross Scientific Advisory Council Burn Cooling Scientific Review

Recommendations:

Standard:

- Monitor for hypothermia when cooling large burns or burns in small children. (Level 5)
- Avoid cooling beyond 40 minutes due to risk of hypothermia. (Level 2b)
- Do not use ice to cool a burn, including an ice pack or bag, due to a risk of worsening the injury. (Level 4)

Guideline:

- Patients who sustain thermal burns should have overlying clothing and jewelry removed (Level 2a, 2b)
- Begin immediate cooling of thermal burns, preferably with cool running water applied to the burn for a minimum of 10 minutes, ideally 20 minutes. (Level 2a, 2b)

Option:

- There may be benefit in cooling a burn up to 3 hours after the injury. (Level 5)
- If cool or cold water is not available, a clean cool or cold compress or cold pack can be used as a substitute to cool thermal burns. (Level 5)

Knowledge Gaps and Future Research:

There is still limited, weak confidence evidence in duration of cooling as well as any other methods that do not require copious amounts of fresh water. Future studies should focus on comparing outcomes for various cooling times as well as investigation into alternatives to cool running water.

Implications for ARC Programs:

The results of this review should be posted on Instructors Corner immediately and incorporated into the First Aid Participants manual with the upcoming revision.

| Log, T. | Modeling of Skin Injury From Hot Spills on Clothing. Int J Environ Res Public Health. 14;11.2017 | Burn. It was able to show that cooling with tap water both increased the exposure duration and temperature needed to cause deeper burns. Given the wide variety of circumstances of a scald, no standard model can define all the variables. | Shorter and lower temperature exposures were needed to cause deep partial thickness burns in children, due to 70% thickness of skin compared to adults. |  |
| Fadeyibi et al | Practice of first aid in burn related injuries in a developing country. Burns. 41:6;1322-32 | An observational study of the types of first aid provided for burns and evaluate how the application of water influenced length of hospital stay, complications, and mortality rate in Lagos, Nigeria. They enrolled 168 patients. It supports the use of water lavage, with lower | Supports | 4E |
complication rates and less area developing into deep burns. Mortality rate was higher in the water lavage group, study authors suspected small sample size and higher rates of petroleum burns in the water lavage group as the cause for this difference. Other limitations included: unclear water source, duration of lavage, or temperature of the water.

Reidling et al Scald burns in children aged 14 and younger in Australia and New Zealand- An analysis based on the Burn Registry of Australia and New Zealand. Burns. 41:3;462-8. 2015

730 children were included in the study. Burns had to be severe enough to require hospitalization, surgical management, or death prior to discharge. They found a high rate of immediate cooling at the scene (89.1%) but only 20.5% received adequate first aid cooling (defined by minimum 20 minutes initiated within 3 hours of burn incident). Authors highlight need for better first aid education as only 1/5 of patients

Retrospective cohort Low Hospital length of stay was significantly shorter for those receiving adequate first aid cooling (2 days versus 2.9 days). No statistical significance in rates of surgical management between inadequate and adequate first aid cooling. This study was limited due to selection bias of patients that required specialized burn center care
